

Universal ratios along a line of critical points.
The Ashkin–Teller model

Abstract

The two-dimensional Ashkin-Teller model provides the simplest example of a statistical system exhibiting a line of critical points along which the critical exponents vary continuously. The scaling limit of both the paramagnetic and ferromagnetic phases separated by the critical line are described by the sine-Gordon quantum field theory in a given range of its dimensionless coupling. After computing the relevant matrix elements of the order and disorder operators in this integrable field theory, we determine the universal amplitude ratios along the critical line within the two-particle approximation in the form factor approach.

1 Introduction

The quantitative description of the universality classes of critical behaviour is the main goal of quantum field theory when applied to statistical mechanics. For a statistical system possessing an isolated point of continuous phase transition the canonical characterisation of the scaling behaviour of a thermodynamic quantity, say the susceptibility χ , takes the form

$$\lim_{t \rightarrow 0^\pm} \chi = \Gamma_\pm |t|^{-\gamma}, \quad (1.1)$$

where $t \sim J_c - J$ measures the distance from the critical temperature $1/J_c$. Direct measures or numerical simulations of the system at different temperatures will then allow the determination of the critical exponent γ and of the critical amplitudes $\Gamma_\pm$. Contrary to the exponent, the amplitudes are not universal, but their ratio Γ_+/Γ_- is [1].

In principle, the universal quantities can be computed from the quantum field theory encoding the fundamental symmetries of the system. The critical exponents are yielded by the massless (conformal) field theory describing the critical point; for the amplitude ratios one needs instead working with the massive (the mass being an increasing function of $|t|$) field theory accounting for the deviations from criticality.

Consider now the case in which the physical system exhibits a manifold of second order phase transition points on which at least some of the critical exponents vary continuously. To be specific, we will refer to the simplest case in which the manifold is a line. Few remarks are in order about the comparison of measurements with theoretical predictions in this situation. The off-critical Hamiltonian of the system contains now two parameters J' and J'' such that the critical line corresponds to a curve in the $J'-J''$ plane. The field theory describing the scaling region close to the critical line will depend on a coupling β (which has nothing to do with inverse temperature) parameterising a line of fixed points of the renormalisation group, as well as on a mass scale measuring the distance from criticality. The correspondence between the values of β and the points of the critical line in the $J'-J''$ plane is non-universal, i.e. it depends on the microscopic details of the system like the lattice structure. For each system in the given universality class, however, this correspondence can be determined comparing measurements and field theoretical predictions for at least one of the universal quantities (say a critical exponent) which vary continuously along the line. Once this has been done, field theory yields predictions for all other universal quantities in much the same way as in the case of isolated critical points.

For a given β , the field theory describes a renormalisation group trajectory flowing away from the point that has been selected on the critical line. Calling t the coordinate along this trajectory, equations like (1.1) now define β -dependent critical exponents and amplitudes. The trouble is that, in the generic case, it is not possible to locate the image of the given trajectory on the $J'-J''$ plane. This means that the path along which the limit has to be taken in (1.1) is not known and this kind of definitions are practically useless for measuring exponents and amplitudes in presence of continuously varying critical behaviour.

While the critical exponents can be measured in other ways (e.g. finite size scaling at criticality), the amplitudes appear essentially out of reach in the present case. For the purpose

of comparison with the field theory predictions, however, we are not interested in the amplitudes themselves, but rather in their universal combinations. If a duality transformation relating points on opposite sides of the critical line on the $J'-J''$ plane is available, an amplitude ratio like Γ_+/Γ_- can in principle be measured without actually measuring the amplitudes. Its value at a given point P_0 along the critical line can be determined taking the ratio of the susceptibility measured at two dual points close to P_0 , the theoretical error going to zero with the distance from P_0 on the $J'-J''$ plane.

This paper deals with the field theoretical determination of universal ratios for the simplest class of continuously varying critical behaviour. Critical phenomena in two dimensions are characterised by a number c , called central charge [2], which increases with the number of degrees of freedom of the system. Since for $c < 1$ critical exponents are only allowed to take discrete values [3], the first possibility for continuously varying exponents opens at $c = 1$. This is the central charge of a free massless boson (Gaussian model), which indeed possesses a continuous one-parameter family of scaling operators. Different statistical models exhibiting a line of critical points with continuously varying exponents renormalise onto the Gaussian model at large distances. These include the Ashkin-Teller model [4] and the 8-vertex model [5], which are related by a duality transformation [6]. Their precise relation at criticality with the Gaussian model has been determined in the past [7] exploiting the exact Baxter solution of the critical 8-vertex model.

The Ashkin-Teller model is not solved on the lattice away from criticality¹ and the universal ratios cannot be computed exactly apart for the special case in which the model reduces to two decoupled Ising models. On the field theoretical side, while the relation of the scaling limit with sine-Gordon type deformations of the Gaussian model has been clear for longtime [8], the quantitative study has been prevented by the need of non-perturbative methods. Here we exploit the integrability of the sine-Gordon model to compute the universal ratios along the Ashkin-Teller critical line in the two-particle approximation within the form factor approach. The form factors of the sine-Gordon model have been and continue to be the subject of intensive study (see [9, 10, 11, 12] among other references). The description of the Ashkin-Teller model, however, relies essentially on the control of the order and disorder operators σ and μ which are not among those considered in these works. We compute all the one- and two-particle matrix elements needed for our purposes within the framework based on the properties of mutual locality between particles and operators. Duality is used to describe through the sine-Gordon field theory both the paramagnetic and ferromagnetic phases on the two sides of the critical line.

The paper is organised as follows. We review the phase diagram of the Ashkin-Teller model in section 2 and its field theoretical description in section 3. Section 4 deals with the scattering theory for the scaling limit around the critical line while section 5 is devoted to form factors. Correlation functions are discussed in sections 6 and universal ratios are computed in section 7 before few concluding remarks.

¹More precisely, away from its self-dual line.

2 The isotropic Ashkin-Teller model on the square lattice

The Ashkin-Teller model [4, 13] describes two Ising models coupled by a four-spin interaction. The case with the two Ising models having the same temperature $1/J$ is called ‘isotropic’ and corresponds to the Hamiltonian

$$H_{AT} = - \sum_{\langle xy \rangle} \{ J[\sigma_1(x)\sigma_1(y) + \sigma_2(x)\sigma_2(y)] + J_4\sigma_1(x)\sigma_1(y)\sigma_2(x)\sigma_2(y) \} , \quad (2.1)$$

where $\sigma_1(x)$ and $\sigma_2(x)$ are the two Ising spins at site x and the sum runs over nearest-neighbour pairs $\langle xy \rangle$. Each of the transformations $\sigma_1 \rightarrow -\sigma_1$, $\sigma_2 \rightarrow -\sigma_2$ and $\sigma_1 \leftrightarrow \sigma_2$ leaves the Hamiltonian invariant.

We are interested in the square lattice model for which the transformation $J \rightarrow -J$ amounts to reversing the spins σ_1 and σ_2 on one sublattice. In this case the phase diagram is symmetric under reflection about the J_4 axis, under which ferromagnetic ordering in σ_1 and σ_2 becomes antiferromagnetic, and vice versa. With this remark in mind we will only refer to the case $J \geq 0$ in the following.

Obviously, the model possesses a critical point in the Ising universality class at $J = J^* \equiv \frac{1}{2} \ln(1 + \sqrt{2})$ along the decoupling line $J_4 = 0$ (the point marked D in Fig. 1). The model becomes invariant under permutations of the four states (σ_1, σ_2) along the line $J = J_4$ which is then the 4-state Potts subspace. Hence, a Potts critical point is located at $J = J_4 = \frac{1}{4} \ln 3$ (point P in Fig. 1). The antiferromagnetic 4-state Potts model on the square lattice is non-critical [14], so that no other critical point for $J > 0$ is implied by the analysis of the Potts subspace.

When $J = 0$, the Hamiltonian (2.1) describes an Ising model in the variable $\sigma_1\sigma_2$. Thus the points I_F and I_{AF} in Fig. 1 located at $J_4 = \pm J^*$ along this line are a ferromagnetic and an antiferromagnetic Ising critical point, respectively.

As $J_4 \rightarrow +\infty$ the energies $\sigma_1(x)\sigma_1(y)$ and $\sigma_2(x)\sigma_2(y)$ take the same value, their product being forced to 1. Thus in this limit the Hamiltonian (2.1) reduces to a single Ising model with coupling $2J$. A ferromagnetic Ising critical point is then located at $(J, J_4) = (J^*/2, +\infty)$.

The model admits a duality transformation [5] which maps the Boltzmann weights

$$\begin{aligned} \omega_1 &= e^{2J+J_4+J_0} \\ \omega_2 &= e^{-J_4+J_0} \\ \omega_3 &= e^{-2J+J_4+J_0} \end{aligned}$$

(J_0 is an arbitrary constant) into the new ones

$$\begin{aligned} \tilde{\omega}_1 &= \frac{1}{2}(\omega_1 + 2\omega_2 + \omega_3) \\ \tilde{\omega}_2 &= \frac{1}{2}(\omega_1 - \omega_3) \\ \tilde{\omega}_3 &= \frac{1}{2}(\omega_1 - 2\omega_2 + \omega_3) . \end{aligned}$$

Figure 1: Phase diagram of the isotropic Ashkin–Teller model on the square lattice. The self-dual curve is divided into a critical line with continuously varying exponents (continuous line) and a non-critical part (dotted line). The dashed curves are critical lines with Ising critical exponents. The dash-dotted line is the 4-state Potts model subspace. Four different phases are labelled by the roman numerals.

For $J > 0$ the weights $\tilde{\omega}_j$ are positive (and the corresponding couplings $\tilde{J}$, $\tilde{J}_4$ and $\tilde{J}_0$ real) provided

$$\cosh 2J > e^{-2J_4} . \quad (2.2)$$

Within the region selected by this condition duality relates points located on opposite sides of the self-dual line determined by the equation

$$\sinh 2J = e^{-2J_4} \quad (2.3)$$

(the line A–D–P–B in Fig. 1).

A duality transformation on the σ_1 spins only maps the square lattice Ashkin–Teller model onto a staggered 8-vertex model [6]. In the isotropic case (2.1) the staggering disappears along the self-dual line (2.3). Since the unstaggered 8-vertex model is exactly solvable, Baxter [5] was able to show that the self-dual line is critical for $J_4 \leq \frac{1}{4} \ln 3$ (curve A–D–P in Fig. 1) and non-critical for $J_4 > \frac{1}{4} \ln 3$ (curve P–B in Fig. 1). The critical exponents vary continuously along the critical portion of the line. We mention that the value $J_4 = J^*/2$ selects on the critical line the Fateev–Zamolodchikov Z_4 -parafermionic critical point [15].

No exact lattice results are available for the model away from the self-dual line. The complete phase diagram, however, has been obtained through a variety of approximate methods (see [16]). The critical line with continuously varying critical exponents bifurcates at the Potts point P into two critical lines, dual of each other, ending into the previously mentioned Ising critical points $(J, J_4) = (J^*/2, +\infty)$ and I_F . Another critical line originates from the antiferromagnetic Ising critical point at I_{AF} and points towards $J_4 \rightarrow -\infty$. The exact location of these three critical lines (dashed in Fig. 1) is unknown. The critical exponents are expected to stay within the Ising universality class along them.

The four critical lines are the boundaries of four different regions in the phase diagram of Fig. 1. In I the system is ferromagnetically ordered with $\langle \sigma_1 \rangle$, $\langle \sigma_2 \rangle$ and $\langle \sigma_1 \sigma_2 \rangle$ all different from zero; phase II is the disordered one in which all these order parameters vanish; phase III exhibits partial ferromagnetic ordering, with $\langle \sigma_1 \rangle = \langle \sigma_2 \rangle = 0$ but $\langle \sigma_1 \sigma_2 \rangle \neq 0$; phase IV is similar to III but with $\sigma_1 \sigma_2$ ordered antiferromagnetically.

3 Scaling limit and field theory

From the field theoretical point of view the critical line with continuously varying exponents of the Ashkin–Teller model must correspond to a line of fixed points of the renormalisation group generated by a marginal operator. The latter can be easily identified looking at the point D on the line where the model reduces to two non-interacting critical Ising models. The four-spin term in (2.1) gives in the continuum limit the product $\varepsilon_1 \varepsilon_2$ of the energy densities of the two Ising models. Since the scaling dimension of the energy operator in the Ising model is 1, $\varepsilon_1 \varepsilon_2$ is indeed marginal. The existence of a line of fixed points implies that this operator remains strictly marginal even away from the decoupling point and is responsible for the deviation of the

critical exponents from the Ising values. Accordingly, we write the action for the scaling limit around the line of fixed points as

$$\mathcal{A}_{scaling} = \mathcal{A}_1^0 + \mathcal{A}_2^0 + \tau \int d^2x (\varepsilon_1(x) + \varepsilon_2(x)) + \rho \int d^2x \varepsilon_1 \varepsilon_2(x), \quad (3.1)$$

where $\mathcal{A}_j^0$, $j = 1, 2$ denotes the fixed point Hamiltonian of the j -th Ising model. The couplings τ and ρ are non-universal functions of the lattice couplings J and J_4 . They determine the distance from criticality and the coordinate along the fixed line, respectively.

The Hamiltonian (3.1) implies that the central charge along the line of fixed points is twice that of the Ising model, namely $c = 1$. This agrees with the fact that the 8-vertex model along its critical line reduces to the 6-vertex model, and the latter renormalises at large distances on a free massless boson, namely the Gaussian model with central charge equal to 1. It is well known [17, 18] that a Gaussian fixed point in two dimensions also admits a description in terms of a Dirac fermion $\psi = \psi_1 + i\psi_2$. The neutral components ψ_j are the Majorana fermions associated to the j -th Ising model. The energy operator ε_j is bilinear in the fermion ($\varepsilon_j = \psi_j^+ \psi_j^-$, with $\psi_j^\pm$ denoting the two components of the spinor), while the spin operator σ_j and the disorder operator μ_j are non-local with respect to it.

The study of the Ashkin-Teller critical line in terms of the Gaussian model was performed in [7]. At the Gaussian fixed point, the boson field can be decomposed into its holomorphic and antiholomorphic parts as $\varphi(x) = \phi(z) + \bar{\phi}(\bar{z})$, where we introduced the complex coordinates $z = x_1 + ix_2$ and $\bar{z} = x_1 - ix_2$. The scaling operators of the theory are the vertex operators

$$V_{p,\bar{p}}(x) = e^{i[p\phi(z) + \bar{p}\bar{\phi}(\bar{z})]}, \quad (3.2)$$

with conformal dimensions $(\Delta, \bar{\Delta}) = (p^2/8\pi, \bar{p}^2/8\pi)$, scaling dimension $X = \Delta + \bar{\Delta}$ and spin $s = \Delta - \bar{\Delta}$. They satisfy the gaussian operator product expansion

$$V_{p_1,\bar{p}_1}(x)V_{p_2,\bar{p}_2}(0) = z^{p_1 p_2/4\pi} \bar{z}^{\bar{p}_1 \bar{p}_2/4\pi} V_{p_1+p_2,\bar{p}_1+\bar{p}_2}(0) + \dots \quad (3.3)$$

We see from this relation that taking $V_{p_1,\bar{p}_1}(x)$ around $V_{p_2,\bar{p}_2}(0)$ by sending $z \rightarrow ze^{2i\pi}$ and $\bar{z} \rightarrow \bar{z}e^{-2i\pi}$ produces a phase factor $e^{2i\pi\gamma_{1,2}}$, where

$$\gamma_{1,2} = \frac{1}{4\pi} (p_1 p_2 - \bar{p}_1 \bar{p}_2) \quad (3.4)$$

is called index of mutual locality. If $\gamma_{1,2}$ is an integer the correlator $\langle V_{p_1,\bar{p}_1}(x)V_{p_2,\bar{p}_2}(0) \rangle$ is single valued and the two operators are said to be mutually local. Since $\gamma_{1,1} = 2s$, the operators which are local with respect to themselves (the only ones we are interested in here) must have integer or half integer spin.

Without loss of generality, we call $\cos\beta\varphi$ the (most relevant component of the) energy operator $\mathcal{E} = \varepsilon_1 + \varepsilon_2$ which drives the system away from criticality. Here β is the parameter which accounts for the continuously varying exponents and then parameterises the critical line; β^2 is equal to 4π at the decoupling point where the scaling dimension of $\mathcal{E}$ must be equal to 1.

All the operators of interest for the description of the lattice model must be local with respect to the energy operator. This locality requirement selects the operators $V_{p,\bar{p}}$ with $p - \bar{p} = 4\pi m/\beta$, m integer, namely

$$V_{p,p}(x) = e^{ip\varphi(x)} \quad (3.5)$$

and

$$U_{n,m}(x) \equiv V_{\frac{n\beta}{2m} + \frac{2\pi}{\beta}m, \frac{n\beta}{2m} - \frac{2\pi}{\beta}m}(x) = e^{i\left[\frac{n\beta}{2m}\varphi(x) + \frac{2\pi}{\beta}m\tilde{\varphi}(x)\right]}, \quad n = 2s = 0, \pm 1, \dots, \quad m = \pm 1, \dots \quad (3.6)$$

Here we introduced the ‘dual’ boson field $\tilde{\varphi}$ which is $\phi(z) - \bar{\phi}(\bar{z})$ at criticality and satisfy the relation

$$i\frac{\partial\tilde{\varphi}}{\partial x_a} = \varepsilon_{ab}\frac{\partial\varphi}{\partial x_b}. \quad (3.7)$$

The operators $e^{ip\varphi}$ and $U_{0,m}$ are scalars ($s = 0$) and have scaling dimensions $X_p = p^2/4\pi$ and $X_{0,m} = \pi m^2/\beta^2$, respectively. The lowest operators with $|s| = 1/2$, i.e. $U_{\pm 1,1}$ and $U_{\pm 1,-1}$ with conformal dimensions $\Delta_{n,m}$ given by

$$\Delta_{\pm 1,1} = \Delta_{\pm 1,-1} = \frac{1}{8} \left(\frac{\beta^2}{4\pi} \pm 2 + \frac{4\pi}{\beta^2} \right) \quad (3.8)$$

$$\bar{\Delta}_{\pm 1,1} = \bar{\Delta}_{\pm 1,-1} = \frac{1}{8} \left(\frac{\beta^2}{4\pi} \mp 2 + \frac{4\pi}{\beta^2} \right), \quad (3.9)$$

form the Dirac spinors

$$\psi = \begin{pmatrix} \psi_+ \\ \psi_- \end{pmatrix} = \begin{pmatrix} \psi_1^+ + i\psi_2^+ \\ \psi_1^- + i\psi_2^- \end{pmatrix} = \begin{pmatrix} U_{1,1} \\ U_{-1,1} \end{pmatrix} \quad (3.10)$$

$$\psi^* = \begin{pmatrix} \psi_+^* \\ \psi_-^* \end{pmatrix} = \begin{pmatrix} \psi_1^+ - i\psi_2^+ \\ \psi_1^- - i\psi_2^- \end{pmatrix} = \begin{pmatrix} U_{1,-1} \\ U_{-1,-1} \end{pmatrix}. \quad (3.11)$$

The Ashkin–Teller operators and their bosonic form [7] are listed in the first two columns of Table 1; the scaling dimensions are given in the third column. The rest of the table specifies the behaviour of the operators under the following transformations:

Spin reversal. We refer to the invariance of the model under the reversal of all σ_1 or all σ_2 spins as $Z_2 \times Z_2$ symmetry. The transformation

$$\begin{aligned} \varphi &\rightarrow -\varphi \\ \frac{2\pi}{\beta}\tilde{\varphi} &\rightarrow \pi - \frac{2\pi}{\beta}\tilde{\varphi} \end{aligned}$$

of the bosonic fields is found to correspond to the reversal of the σ_1 spins. The transformation

$$\begin{aligned} \varphi &\rightarrow -\varphi \\ \tilde{\varphi} &\rightarrow -\tilde{\varphi} \end{aligned}$$

corresponds instead to the reversal of the σ_2 spins.

Table 1: Ashkin-Teller operators with their bosonic counterparts, scaling dimensions and symmetry properties. When a symmetry transformation sends an operator into $\pm$ itself, only $\pm$ is indicated.

Exchange . The exchange of the two Ising copies ($1 \leftrightarrow 2$) is implemented in the bosonic language by the transformation

$$\begin{aligned}\varphi &\rightarrow -\varphi \\ \frac{2\pi}{\beta}\tilde{\varphi} &\rightarrow \frac{\pi}{2} - \frac{2\pi}{\beta}\tilde{\varphi}.\end{aligned}$$

Semi-duality . We call semi-duality the transformation D_j which interchanges σ_j and μ_j . We saw in the previous section that a transformation of this kind relates the Ashkin-Teller model to the 8-vertex model. In the bosonic language D_1 corresponds to the exchange

$$\frac{\beta}{2}\varphi \leftrightarrow -\frac{2\pi}{\beta}\tilde{\varphi}. \quad (3.12)$$

and D_2 to

$$\frac{\beta}{2}\varphi \leftrightarrow \frac{\pi}{2} - \frac{2\pi}{\beta}\tilde{\varphi} \quad (3.13)$$

Clearly $D_j^2 = 1$. Notice that D_1 is not quite the duality transformation of the first Ising model. In particular, it changes the sign of ε_2 rather than ε_1 . A similar observation applies to D_2 .

Duality . This is the full duality transformation of the Ashkin–Teller model and is obtained composing D_1 and D_2 . Due to sign factors there are two possibilities, $D_+ = D_1 D_2$ and $D_- = D_2 D_1$. $D_{\pm}$ correspond to the bosonic transformations

$$\begin{aligned}\beta\varphi &\rightarrow \beta\varphi \pm \pi \\ \frac{2\pi}{\beta} \tilde{\varphi} &\rightarrow \frac{2\pi}{\beta} \tilde{\varphi} \pm \frac{\pi}{2} .\end{aligned}$$

Notice that $D_+ D_- = D_- D_+ = 1$, $D_{\pm}^2 \neq 1$.

3.1 The self–dual line

The field theory describing the self-dual line (2.3) at large distances has to be invariant under all the above transformations. This requirement selects the action

$$\mathcal{A}_{sd} = \int d^2x \left[\frac{1}{2} (\partial_a \varphi)^2 - \sum_n \left(g_n \cos 2n\beta\varphi + \tilde{g}_n \cos 8n \frac{\pi}{\beta} \tilde{\varphi} \right) \right] , \quad (3.14)$$

where the g_n ’s and $\tilde{g}_n$ ’s are, like β , non-universal functions of J_4 . This theory is critical (massless) as long as none of the operators perturbing the Gaussian term becomes relevant. Since $\cos 2\beta\varphi$ becomes marginal at $\beta^2 = 2\pi$ and $\cos 8\pi\tilde{\varphi}/\beta$ at $\beta^2 = 8\pi$, the critical range is $2\pi \leq \beta^2 \leq 8\pi$.

The 4-state Potts critical point (P in Fig. 1) is the right end point of the Ashkin–Teller critical line. At this point the Ising variables σ_1 , σ_2 and $\sigma_1\sigma_2$ play a completely symmetric role and must have the same scaling dimension $1/8$. Hence, it follows from Table 1 that the Potts point corresponds to $\beta^2 = 2\pi$.

The relation between β and J_4 along the critical line for the case of the square lattice model with nearest neighbour interactions can be obtained comparing the energy scaling dimension predicted by the Gaussian theory with that coming from the lattice solution. It reads [7]

$$\frac{4\pi}{\beta^2} = 1 - \frac{2}{\pi} \arcsin \left(\frac{\tanh 2J_4}{\tanh 2J_4 - 1} \right) , \quad (3.15)$$

from which we see that the limit $J_4 \rightarrow -\infty$ corresponds to $\beta^2 = 6\pi$. Thus the Ashkin–Teller critical line with continuously varying exponents spans only a portion of the critical region of the theory (3.14), namely the range

$$2\pi \leq \beta^2 < 6\pi . \quad (3.16)$$

For $\beta^2 < 2\pi$ at least one of the operators $\cos 2n\beta\varphi$ is relevant. The theory (3.14) is massive and corresponds to the non-critical part of the self-dual line. The relation (3.15) does not hold in this region.

3.2 Breaking duality

The field theory describing the model on the two sides of the self–dual line is obtained adding to the self–dual action (3.14) the operators $\cos(2n-1)\beta\varphi$, which preserve the spin reversal and

exchange symmetries but are odd under duality

$$\mathcal{A}_{AT} = \mathcal{A}_{sd} - \sum_n \tau_n \int d^2x \cos(2n-1)\beta\varphi, \quad (3.17)$$

where the τ_n 's are functions of the lattice couplings J and J_4 .

To describe the scaling regions around the critical line with continuously varying exponents we keep the only operator which is relevant in the range (3.16). Thus we are left with the euclidean sine-Gordon action (we set $\tau_1 = \tau$)

$$\mathcal{A}_{SG} = \int d^2x \left(\frac{1}{2} (\partial_a \varphi)^2 - \tau \cos \beta\varphi \right) \quad (3.18)$$

which is the bosonic version of (3.1).

For $\tau > 0$ this action describes the scaling region of the paramagnetic phase II in which the vacuum $|0\rangle$ located at $\varphi = 0$ is invariant under spin reversal and exchange symmetry and we have

$$\begin{aligned} \langle 0 | \sigma_1 | 0 \rangle &= \langle 0 | \sigma_2 | 0 \rangle = 0 \\ \langle 0 | \sigma_1 \sigma_2 | 0 \rangle &= \langle 0 | \sin \frac{\beta\varphi}{2} | 0 \rangle = 0. \end{aligned}$$

For $\tau < 0$ the two vacua $|0_\pm\rangle$ located at $\beta\varphi = \pm\pi$ are the image of the high-temperature vacuum $|0\rangle$ through the duality transformations $D_\pm$. The vacua $|0_+\rangle$ and $|0_-\rangle$ are interchanged by the spin reversal and exchange transformations, so that the internal symmetries of the model are spontaneously broken (ferromagnetic phase I). We have

$$\begin{aligned} \langle 0_+ | \sigma_1 | 0_+ \rangle &= \langle 0_+ | \sigma_2 | 0_+ \rangle = \pm M_\sigma \\ \langle 0_- | \sigma_1 | 0_- \rangle &= -\langle 0_- | \sigma_2 | 0_- \rangle = \pm M_\sigma \\ \langle 0_\pm | \sigma_1 \sigma_2 | 0_\pm \rangle &= \langle 0_\pm | \sin \frac{\beta\varphi}{2} | 0_\pm \rangle = \pm M_\mathcal{P} \end{aligned}$$

where M_σ and $M_\mathcal{P}$ are positive. The last equation follows from the relations

$$\begin{aligned} \langle 0_+ | e^{i\alpha\varphi} | 0_+ \rangle &= \langle 0_- | e^{-i\alpha\varphi} | 0_- \rangle \\ \langle 0_\pm | e^{i\alpha\varphi} | 0_\pm \rangle &= e^{\pm 2i\pi\alpha/\beta} \langle 0_\pm | e^{-i\alpha\varphi} | 0_\pm \rangle. \end{aligned}$$

3.3 Bifurcation at the Potts critical point

For $\beta^2 < 2\pi$ more operators become relevant in the action (3.17). Neglecting all irrelevant terms in the range $8\pi/9 < \beta^2 < 2\pi$ leads to the double sine-Gordon action ($g_1 \equiv g$) [8]

$$\mathcal{A}_{DSG} = \int d^2x \left(\frac{1}{2} (\partial_a \varphi)^2 - \tau \cos \beta\varphi - g \cos 2\beta\varphi \right). \quad (3.19)$$

This quantum field theory has been analysed in Ref. [19]. The mechanism through which it accounts for the bifurcation of the critical line at the Potts critical point is easily understood already at the classical level. To see this let us fix a value of β in the considered range and

Figure 2: Schematic phase diagram of the double sine-Gordon quantum field theory (3.19) for fixed $\beta^2 < 2\pi$. Two massless trajectories starting from the Gaussian fixed point at the origin flow towards infrared Ising fixed points and divide the plane into three different phases. The points at $\pm\tau_c$ on these trajectories correspond to dual points along the Ising critical lines bifurcating from point P in Fig. 1.

treat for a moment both τ and g as free parameters. For $g = 0$ and fixed $\tau > 0$ the vacuum of the theory (3.19) (i.e. the minimum of the potential invariant under the symmetries of the paramagnetic phase) is located at $\varphi = 0$. It stays there as we decrease g down to a critical value g_c , classically equal to $-\tau/4$, where the quadratic term of the potential vanishes. For $g < g_c$ we have a maximum at $\varphi = 0$ and two new minima located symmetrically with respect to it. Thus an Ising phase transition occurred at g_c . Similar considerations can be repeated for $\tau < 0$ (starting with one of the vacua at $\varphi = \pm\pi$ for $g = 0$) and the resulting picture can be confirmed at the quantum level [19]. In summary, the lower τ - g half plane is divided into three regions (Fig. 2) by two massless trajectories (corresponding classically to $g = \pm\tau/4$ but whose precise location is unknown in the quantum theory) along which a flow from the Gaussian fixed point at the origin to infrared Ising fixed points takes place. Region II is a paramagnetic phase where the vacuum is located at $\varphi = 0$; region I is a ferromagnetic phase dual to II where $\langle\beta\varphi\rangle$ equals π or $-\pi$; in region III $\langle\beta\varphi\rangle$ interpolates smoothly from 0 to $\pm\pi$ taking the value $\pm\pi/2$ at $\tau = 0$. In this latter phase we have $\langle\sigma_1\sigma_2\rangle \neq 0$; it is less clear to us how to argue that $\langle\sigma_1\rangle = \langle\sigma_2\rangle = 0$.

In order to make contact with the phase diagram of Fig. 1 we need to recall that g is not a free parameter at fixed β . Indeed, both β and g are determined by the value that J_4 takes along the self-dual line. It is the value $g(\beta^2)$ that determines the distance τ_c of the Ising transition points from the given point along the self-dual line (see Fig. 2). The phase diagram requires that $g(\beta^2)$ vanishes at $\beta^2 = 2\pi$ and then decreases with β^2 . The result in the coupling space of

Figure 3: Like in Fig. 2 but with varying β^2 . The oriented lines indicate the flow towards larger distances along the critical surfaces. The thick lines are determined by the intersection of these critical surfaces with the image of the J - J_4 plane of Fig. 1.

the theory (3.19) is shown in Fig. 3. For $\pi/2 < \beta^2 < 2\pi$ the non-critical part of the self-dual line is described by the action (3.19) with $\tau = 0$. As the Potts critical point is approached from below along the line ($\beta^2 \rightarrow 2\pi^-$, $g \rightarrow 0^-$) the operator $\cos 2\beta\varphi$ becomes marginally relevant implying an exponential rather than power law divergence of the correlation length. The same massive field theory describes the $q \rightarrow 4^+$ limit of the q -state Potts model at $T = T_c$ [20].

4 Scattering theory

According to the discussion of the previous section the scaling limit of the Ashkin–Teller model around the critical line with continuously varying exponents is described by the sine-Gordon theory (3.18). This quantum field theory is integrable and the associated elastic and factorised scattering matrix is exactly known ([21] and references therein).

The elementary excitations are the soliton A_+ and antisoliton A_- which interpolate between adjacent vacua of the periodic potential. While being topologic excitations of the bosonic action (3.18) they correspond to the fermions ψ and ψ^* of the equivalent fermionic model (the massive Thirring model) [17, 18]. Actually, the integer m in (3.6) measures precisely the topologic charge and all the operators with $m = 1$ (-1) create a soliton (antisoliton) when acting on the vacuum of the theory. Writing $A_{\pm} = (A_1 \pm iA_2)/\sqrt{2}$, the operators ψ_i and $\sigma_i \mu_{i+1 \pmod{2}}$ are both suitable interpolating operators for the neutral component A_i . To be definite, we will refer to

Figure 4: Simple pole diagram associated to Eq. (4.7).

the latter choice in the following (see Table 2). The scattering of the particles A_1 and A_2 in the integrable theory is completely determined by the relations²

$$A_i(\theta_1)A_j(\theta_2) = \sum_{k,l=1,2} S_{A_i A_j}^{A_k A_l}(\theta_1 - \theta_2) A_l(\theta_2) A_k(\theta_1) \quad (4.1)$$

with the non-zero scattering amplitudes given by [21]

$$\begin{aligned} S_{A_1 A_1}^{A_1 A_1}(\theta) &= S_{A_2 A_2}^{A_2 A_2}(\theta) = \frac{S(\theta) + S_+(\theta)}{2} \\ S_{A_1 A_1}^{A_2 A_2}(\theta) &= S_{A_2 A_2}^{A_1 A_1}(\theta) = \frac{S_+(\theta) - S(\theta)}{2} \\ S_{A_1 A_2}^{A_1 A_2}(\theta) &= S_{A_2 A_1}^{A_2 A_1}(\theta) = \frac{S(\theta) + S_-(\theta)}{2} \\ S_{A_1 A_2}^{A_2 A_1}(\theta) &= S_{A_2 A_1}^{A_1 A_2}(\theta) = \frac{S(\theta) - S_-(\theta)}{2}, \end{aligned} \quad (4.2)$$

where

$$\begin{aligned} S_+(\theta) &= -\frac{\sinh \frac{\pi}{2\xi}(\theta + i\pi)}{\sinh \frac{\pi}{2\xi}(\theta - i\pi)} S(\theta) \\ S_-(\theta) &= -\frac{\cosh \frac{\pi}{2\xi}(\theta + i\pi)}{\cosh \frac{\pi}{2\xi}(\theta - i\pi)} S(\theta) \\ S(\theta) &= -\exp \left\{ -i \int_0^\infty \frac{dx}{x} \frac{\sinh \frac{x}{2} \left(1 - \frac{\xi}{\pi}\right)}{\sinh \frac{x\xi}{2\pi} \cosh \frac{x}{2}} \sin \frac{\theta x}{\pi} \right\} \\ \xi &= \frac{\pi\beta^2}{8\pi - \beta^2}. \end{aligned}$$

²The on-shell energy and momentum of a particle of species a are parameterised as $(p^0, p^1) = (m_a \cosh \theta, m_a \sinh \theta)$.

For $\beta^2 < 4\pi$ (attractive regime) the above amplitudes possess simple poles in the physical strip $\text{Im}\theta \in (0, \pi)$ corresponding to bound states (breathers) B_n . The poles are located at $\theta = i(\pi - n\xi)$ (n even for $S_+(\theta)$ and odd for $S_-(\theta)$) and determine the masses of the breathers

$$m_n = 2M \sin \frac{n\xi}{2}, \quad 1 \leq n < \left\lceil \frac{\pi}{\xi} \right\rceil \quad (4.3)$$

where M is the mass of the particles A_j and $[x]$ denotes the integer part of x . The lightest breather B_1 is the particle interpolated by the boson φ and then is odd under all the internal symmetries of the model. The breather B_n can be seen as a bound state of n breathers B_1 , so that its symmetry properties are those summarised in Table 2.

Particle	Creating operator	$Z_2 \times Z_2$	$1 \leftrightarrow 2$
A_1	$\sigma_1 \mu_2$	$- \times +$	A_2
A_2	$\mu_1 \sigma_2$	$+ \times -$	A_1
B_{2k+1}	$\sin \beta \varphi$	$- \times -$	$-$
B_{2k}	$\cos \beta \varphi$	$+ \times +$	$+$

Table 2: Particles, interpolating operators and their symmetries.

The scattering of the breathers with the elementary excitations and with themselves is completely diagonal (initial and final states are identical). The corresponding amplitudes are

$$S_{A_j B_n}(\theta) = t_{\frac{1}{2} + \frac{n\xi}{2\pi}}(\theta) \times \begin{cases} \prod_{j=1}^{(n-1)/2} t_{\frac{1}{2} + (n-2j)\frac{\xi}{2\pi}}^2(\theta), & n \text{ odd} \\ t_{\frac{1}{2}}(\theta) \prod_{j=1}^{(n-2)/2} t_{\frac{1}{2} + (n-2j)\frac{\xi}{2\pi}}^2(\theta), & n \text{ even} \end{cases} \quad (4.4)$$

$$S_{B_m B_n}(\theta) = t_{(m+n)\frac{\xi}{2\pi}}(\theta) t_{1-|m-n|\frac{\xi}{2\pi}}(\theta) \prod_{j=1}^{\min(m,n)-1} t_{(|m-n|+2j)\frac{\xi}{2\pi}}^2(\theta) \quad (4.5)$$

where

$$t_\alpha(\theta) = \frac{\tanh \frac{1}{2}(\theta + i\pi\alpha)}{\tanh \frac{1}{2}(\theta - i\pi\alpha)}. \quad (4.6)$$

The simple pole at $\theta = i(\pi + n\xi)/2$ in the amplitude $S_{A_j B_n}(\theta)$ corresponds to the appearance as a bound state in the channel $A_j B_n$ of the particle $A_{j+1 \pmod{2}}$ (n odd) or A_j (n even). The simple pole at $\theta = i(n+m)\xi/2$ ($\theta = i[\pi - |n-m|\xi/2]$) in the amplitude $S_{B_m B_n}(\theta)$ signals that B_{n+m} ($B_{|n-m|}$) appears as a bound state in the $B_m B_n$ channel. A crossed channel pole located at $i\pi - \theta$ is associated to each of these direct channel poles. A direct channel pole at $\theta = iu_{ab}^c$ corresponding to the particle c appearing as bound state in the ab channel allows the determination of the three-particle coupling Γ_{ab}^c through the relation (see Fig. 4)

$$S_{ab}(\theta \simeq iu_{ab}^c) \simeq i \frac{\Gamma_{ab}^c \Gamma_c^{ab}}{\theta - iu_{ab}^c} \quad (4.7)$$

Figure 5: Double pole diagram associated to Eq. (4.8).

where $\Gamma_c^{ab} = C_a C_b C_c \Gamma_{ab}^c$, $\Gamma_{ab}^c = C_a C_c \Gamma_{bc}^a$ with $C_{A_j} = 1$, $C_{B_n} = (-1)^n$. We also note the property $\Gamma_{A_i A_j}^{B_n} = (-1)^{i+j} \Gamma_{A_j A_i}^{B_n}$.

The second order poles do not correspond to bound states and can be explained in terms of multiscattering processes of the type shown in Fig. 5 [22, 23]. In the vicinity of such a pole located at $\theta = i\varphi$ the scattering amplitude can be written as

$$S_{ab}(\theta \simeq i\varphi) \simeq \frac{\Gamma_{ad}^c \Gamma_{db}^e \Gamma_c^{ad} \Gamma_e^{db} S_{ce}(i\eta)}{(\theta - i\varphi)^2} . \quad (4.8)$$

5 Form factors

The knowledge of the scattering amplitudes allows the determination of the form factors

$$F_{a_1 \dots a_n}^\Phi(\theta_1, \dots, \theta_n) = \langle 0 | \Phi(0) | a_1(\theta_1) \dots a_n(\theta_n) \rangle . \quad (5.1)$$

Many results are known about the form factors of the sine-Gordon model [9, 10, 11, 12]. Here we will recall how the one- and two-particle form factors can be computed within the general approach. These matrix elements for the order and disorder operators σ_j and μ_j , which are crucial for the description of the Ashkin–Teller model, were first considered in [24].

We use for the two-particle form factors of a scalar operator $\Phi(x)$ the notation

$$F_{ab}^\Phi(\theta_1 - \theta_2) = \langle 0 | \Phi(0) | a(\theta_1) b(\theta_2) \rangle , \quad (5.2)$$

the dependence on the rapidity difference being a consequence of Lorentz invariance. The matrix elements satisfy the equations [9, 10, 25]

$$F_{ab}^\Phi(\theta) = S_{ab}^{cd}(\theta) F_{dc}^\Phi(-\theta) \quad (5.3)$$

$$F_{ab}^\Phi(\theta + 2i\pi) = l_{\Phi,a} F_{ba}^\Phi(-\theta) \quad (5.4)$$

$$\text{Res}_{\theta=i\pi} F_{ab}^\Phi(\theta) = i\delta_{ab} (1 - l_{\Phi,a}) \langle \Phi \rangle \quad (5.5)$$

$$\text{Res}_{\theta=iu_{ab}^c} F_{ab}^\Phi(\theta) = i\Gamma_{ab}^c F_c^\Phi \quad (5.6)$$

where the factor $l_{\Phi,a}$ takes into account the mutual locality between Φ and the particle a (see Table 3). If ϕ_a is the operator which interpolates the particle a , then $l_{\Phi,a} = e^{2i\pi\gamma_{\Phi,\phi_a}}$. For the operators having a bosonic expression, γ_{Φ,ϕ_a} is given by (3.4). For σ_j and μ_j the results of Table 3 follow from the properties $l_{\sigma_j,\sigma_k} = l_{\mu_j,\mu_k} = 1$ and $l_{\sigma_j,\mu_k} = (-1)^{\delta_{jk}}$ (notice that the even breathers appear in the $A_j A_j$ channel while the odd ones appear in the $A_1 A_2$ channel).

Φ	Bosonic form	l_{Φ,A_j}	l_{Φ,B_n}
σ_i		$(-1)^{\delta_{ij}+1}$	$(-1)^n$
μ_i		$(-1)^{\delta_{ij}}$	$(-1)^n$
$\mathcal{E} = \varepsilon_1 + \varepsilon_2$	$\cos \beta\varphi$	+1	+1
$\mathcal{C} = \varepsilon_1 - \varepsilon_2$	$\cos \frac{4\pi}{\beta} \tilde{\varphi}$	+1	+1
$\mathcal{E}_+ = \bar{\psi}_1 \psi_2 + \bar{\psi}_2 \psi_1$	$\sin \frac{4\pi}{\beta} \tilde{\varphi}$	+1	+1
$\mathcal{E}_- = \bar{\psi}_1 \psi_2 - \bar{\psi}_2 \psi_1$	$\sin \beta\varphi$	+1	+1
$\mathcal{P} = \sigma_1 \sigma_2$	$\sin \frac{\beta}{2} \varphi$	-1	+1
$\mathcal{P}^* = \mu_1 \mu_2$	$\cos \frac{\beta}{2} \varphi$	-1	+1
$\sigma_1 \mu_2$	$\cos \frac{2\pi}{\beta} \tilde{\varphi}$	+1	+1
$\mu_1 \sigma_2$	$\sin \frac{2\pi}{\beta} \tilde{\varphi}$	+1	+1

Table 3: Factors of mutual locality between particles and operators entering Eqs. (5.4) and (5.5).

The form factors are further constrained by the asymptotic bound [26]

$$\lim_{|\theta| \rightarrow \infty} F_{ab}^\Phi(\theta) \sim e^{y_\Phi |\theta|} \quad (5.7)$$

$$y_\Phi \leq \frac{X_\Phi}{2}, \quad (5.8)$$

where X_Φ is the operator scaling dimension. The non-zero two-particle matrix elements on the elementary excitations A_1 and A_2 in the disordered phase are then uniquely determined to be

$$F_{A_j A_j}^{\mu_i}(\theta) = \frac{i\pi \langle \mu \rangle}{2\xi \omega(i\pi)} \frac{F_0(\theta)}{\sinh \frac{\pi}{2\xi}(\theta - i\pi)} \left[\omega(\theta) + (-1)^{l+j} \omega(2i\pi - \theta) \right] \quad (5.9)$$

$$F_{A_j A_j}^{\mathcal{E}}(\theta) = ic_1 \frac{\cosh \frac{\theta}{2}}{\sinh \frac{\pi}{2\xi}(\theta - i\pi)} F_0(\theta) \quad (5.10)$$

$$F_{A_j A_j}^{\mathcal{C}}(\theta) = c_2 (-1)^j F_0(\theta) \quad (5.11)$$

$$F_{A_1 A_2}^{\mathcal{E}_+}(\theta) = F_{A_2 A_1}^{\mathcal{E}_+}(\theta) = ic_2 F_0(\theta) \quad (5.12)$$

$$F_{A_1 A_2}^{\mathcal{E}_-}(\theta) = -F_{A_2 A_1}^{\mathcal{E}_-}(\theta) = -c_1 \frac{\cosh \frac{\theta}{2}}{\cosh \frac{\pi}{2\xi}(\theta - i\pi)} F_0(\theta) \quad (5.13)$$

$$F_{A_1 A_2}^{\mathcal{P}}(\theta) = -F_{A_2 A_1}^{\mathcal{P}}(\theta) = -\frac{\pi}{\xi} \langle \mathcal{P}^* \rangle \frac{F_0(\theta)}{\cosh \frac{\pi}{2\xi}(\theta - i\pi)} \quad (5.14)$$

$$F_{A_j A_j}^{\mathcal{P}^*}(\theta) = \frac{i\pi}{\xi} \langle \mathcal{P}^* \rangle \frac{F_0(\theta)}{\sinh \frac{\pi}{2\xi}(\theta - i\pi)} . \quad (5.15)$$

Here c_1 and c_2 are normalisation constants, $\langle \mu \rangle \equiv \langle \mu_1 \rangle = \langle \mu_2 \rangle$, and the functions

$$\omega(\theta) = \exp \left\{ 2 \int_0^\infty \frac{dx}{x} \frac{\sinh \left(1 - \frac{\xi}{\pi} \right) x}{\sinh \frac{x\xi}{\pi}} \frac{\sin^2 \frac{\theta x}{2\pi}}{\sinh 2x} \right\} \quad (5.16)$$

$$F_0(\theta) = -i \sinh \frac{\theta}{2} \exp \left\{ \int_0^\infty \frac{dx}{x} \frac{\sinh \frac{x}{2} \left(1 - \frac{\xi}{\pi} \right)}{\sinh \frac{x\xi}{2\pi} \cosh \frac{x}{2}} \frac{\sin^2 \frac{(i\pi - \theta)x}{2\pi}}{\sinh x} \right\} \quad (5.17)$$

satisfy the equations

$$\omega(\theta) = \omega(-\theta) , \quad \omega(\theta + 2i\pi) = -\frac{\sinh \frac{\pi}{2\xi}(\theta + i\pi)}{\sinh \frac{\pi}{2\xi}(\theta - i\pi)} \omega(\theta - 2i\pi) \quad (5.18)$$

$$F_0(\theta) = S(\theta) F_0(-\theta) , \quad F_0(\theta + 2i\pi) = F_0(-\theta) . \quad (5.19)$$

For large values of $|\theta|$ they behave as

$$\omega(\theta) \sim \exp \left[\left(\frac{\pi}{\xi} - 1 \right) \frac{|\theta|}{4} \right] \quad (5.20)$$

$$F_0(\theta) \sim \exp \left[\left(\frac{\pi}{\xi} + 1 \right) \frac{|\theta|}{4} \right] . \quad (5.21)$$

For $\xi < \pi/2$, the analytic continuation

$$\begin{aligned} \omega(2i\pi - \theta) &= -\frac{\sinh[(\theta - i(\pi - 2\xi))/4] \sinh[(\theta + i(\pi - 2\xi))/4]}{\cos^2[(\pi - 2\xi)/4]} \\ &\times \exp \left\{ 2 \int_0^\infty \frac{dx}{x} \frac{\sinh \left(1 - \frac{3\xi}{\pi} \right) x}{\sinh \frac{x\xi}{\pi} \sinh 2x} \sin^2 \frac{(2i\pi - \theta)x}{2\pi} \right\} \end{aligned} \quad (5.22)$$

is convergent for real rapidity values.

The breather-breather form factors can be written in the form

$$F_{B_n B_m}^\Phi(\theta) = P_{B_n B_m}^\Phi(\theta) \left(\cosh \frac{\theta}{2} \right)^{\frac{1}{2}(1-l_{\Phi, B_n})(-1)^{\delta_{n,m}}} \frac{F_{B_n B_m}^{min}(\theta)}{D_{B_n B_m}(\theta)} . \quad (5.23)$$

Here

$$F_{B_m B_n}^{min}(\theta) = T_{(m+n)\frac{\xi}{2\pi}}(\theta) T_{1-|m-n|\frac{\xi}{2\pi}}(\theta) \prod_{j=1}^{\min(m,n)-1} T_{(|m-n|+2j)\frac{\xi}{2\pi}}^2(\theta) . \quad (5.24)$$

The function

$$T_\alpha(\theta) = \exp \left\{ 2 \int_0^\infty \frac{dt}{t} \frac{\cosh \left(\alpha - \frac{1}{2} \right) t}{\cosh \frac{t}{2} \sinh t} \sin^2 \frac{(i\pi - \theta)t}{2\pi} \right\} \quad (5.25)$$

solves the equations

$$T_\alpha(\theta) = -t_\alpha(\theta)T_\alpha(-\theta), \quad T_\alpha(\theta + 2i\pi) = T_\alpha(-\theta) \quad (5.26)$$

and behaves asymptotically as

$$T_\alpha(\theta) \sim \exp(|\theta|/2), \quad |\theta| \rightarrow \infty. \quad (5.27)$$

In particular

$$T_0(\theta) = T_1(\theta) = -i \sinh \frac{\theta}{2}. \quad (5.28)$$

The denominator $D_{B_n B_m}(\theta)$ in (5.23) accounts for the pole structure of the form factors and can be written as (see [26])

$$D_{B_m B_n}(\theta) = \mathcal{P}_{(m+n)\frac{\varepsilon}{2\pi}}(\theta) \mathcal{P}_{1-|m-n|\frac{\varepsilon}{2\pi}}(\theta) \prod_{j=1}^{\min(m,n)-1} \mathcal{W}_{(|m-n|+2j)\frac{\varepsilon}{2\pi}}(\theta) \quad (5.29)$$

with

$$\mathcal{P}_\alpha(\theta) = \frac{\cos \pi \alpha - \cosh \theta}{2 \cos^2 \frac{\pi \alpha}{2}}, \quad \alpha \neq 1 \quad (5.30)$$

$$\mathcal{P}_1(\theta) = 1 \quad (5.31)$$

$$\mathcal{W}_\alpha(\theta) = \mathcal{P}_\alpha(\theta) \mathcal{P}_{1-\alpha}(\theta). \quad (5.32)$$

The last ingredient of (5.23) are the polynomials

$$P_{ab}^\Phi(\theta) = \sum_{k=0}^{N_{ab}^\Phi} c_{ab}^{\Phi;k} (\cosh \theta)^k \quad (5.33)$$

whose total degree is constrained by the asymptotic bound (5.8) and whose coefficients are determined by the residue equations (5.5) and (5.6) together³ with the relation [26]

$$F_{ab}^\Phi(\theta \simeq i\varphi) \simeq i \frac{\Gamma_{ad}^c \Gamma_{db}^e F_{ce}^\Phi(i\eta)}{\theta - i\varphi} \quad (5.34)$$

associated to the double poles (4.8) in the scattering amplitudes. In particular, one finds $N_{B_1 B_1}^\Phi = 0$ and $N_{B_2 B_2}^\Phi = 1$ for $\Phi = \mu, \mathcal{E}, \mathcal{P}^*$, and $N_{B_1 B_2}^\mathcal{P} = 1$.

Concerning the channel $A_j B_n$, the property

$$F_{A_j B_n}^\Phi(\theta) = (-1)^n F_{B_n A_j}^\Phi(\theta) \quad (5.35)$$

has to be taken into account. We find that the minus sign appearing for odd breathers (and implying $\Gamma_{A_j B_{2k+1}}^{A_{j+1} \text{ (mod } 2)} = -\Gamma_{B_{2k+1} A_j}^{A_{j+1} \text{ (mod } 2)}$) is needed if solutions compatible with the asymptotic bound (5.8) are to be found for the operators σ_i and $\sigma_i \mu_{i+1 \text{ (mod } 2)}$. Then one can write

$$F_{A_j B_n}^\Phi(\theta) = P_{A_j B_n}^\Phi(\theta) \left(\cosh \frac{\theta}{2} \right)^{\delta_{n, \text{odd}} \delta_{1, l_\Phi, B_n}} \frac{F_{A_j B_n}^{\text{min}}(\theta)}{D_{A_j B_n}(\theta)}, \quad (5.36)$$

³See also (6.6) for the energy operator $\mathcal{E}(x)$.

where

$$F_{A_j B_n}^{min}(\theta) = \prod_{j=0}^{n-1} T_{\frac{1}{2}+(n-2j)\frac{\xi}{2\pi}}(\theta) \quad (5.37)$$

$$D_{A_j B_n}(\theta) = \mathcal{P}_{\frac{1}{2}+\frac{n\xi}{2\pi}}(\theta) \times \begin{cases} \prod_{j=1}^{(n-1)/2} \mathcal{W}_{\frac{1}{2}+(n-2j)\frac{\xi}{2\pi}}(\theta), & n \text{ odd} \\ \mathcal{P}_{\frac{1}{2}}(\theta) \prod_{j=1}^{(n-2)/2} \mathcal{W}_{\frac{1}{2}+(n-2j)\frac{\xi}{2\pi}}(\theta), & n \text{ even} \end{cases} \quad (5.38)$$

and $P_{A_j B_n}^\Phi(\theta)$ are polynomials in $\cosh \theta$ to be fixed through the conditions on the poles. In particular we have

$$F_{A_j B_1}^{\sigma_{j+1} \pmod{2}}(\theta) = -F_{B_1 A_j}^{\sigma_{j+1} \pmod{2}}(\theta) = (-1)^j a \frac{T_{(1+\xi/\pi)/2}(\theta)}{\mathcal{P}_{(1+\xi/\pi)/2}(\theta)} \quad (5.39)$$

$$F_{A_j B_2}^{\sigma_j}(\theta) = F_{B_2 A_j}^{\sigma_j}(\theta) = (b \cosh \theta + c) \frac{T_{1/2}(\theta) T_{1/2+\xi/\pi}(\theta)}{\mathcal{P}_{1/2}(\theta) \mathcal{P}_{1/2+\xi/\pi}(\theta)} \quad (5.40)$$

with a , b and c determined by the equations

$$\text{Res}_{\theta=i(\pi+\xi)/2} F_{A_1 B_1}^{\sigma_2}(\theta) = i \Gamma_{A_1 B_1}^{A_2} F_{A_2}^{\sigma_2} \quad (5.41)$$

$$\text{Res}_{\theta=i(\pi/2+\xi)} F_{A_2 B_2}^{\sigma_2}(\theta) = i \Gamma_{A_2 B_2}^{A_2} F_{A_2}^{\sigma_2} \quad (5.42)$$

$$\text{Res}_{\theta=i\pi/2} F_{A_2 B_2}^{\sigma_2}(\theta) = i \Gamma_{A_2 B_1}^{A_1} \Gamma_{B_1 B_2}^{B_1} F_{A_1 B_1}^{\sigma_2}(i(\pi - 3\xi)/2) . \quad (5.43)$$

The last equation is the specialisation of (5.34) to the double pole appearing at $\theta = i\pi/2$ in the $A_j B_{2k}$ scattering amplitudes and related to the diagram of Fig. 5 with $a = A_j$, $b = B_{2k}$, $d = e = B_k$ and $c = A_i$, $i = j$ ($i \neq j$) for k even (odd). It can be checked that the matrix elements (5.40) determined in this way satisfy the asymptotic factorisation condition [28]

$$\lim_{\theta \rightarrow \infty} F_{A_j B_{2k}}^{\sigma_j}(\theta) = F_{A_j}^{\sigma_j} \frac{F_{B_{2k}}^{\mu_i}}{\langle \mu \rangle} \quad (5.44)$$

with $k = 1$. The condition

$$\lim_{\theta \rightarrow \infty} |F_{A_j A_j}^{\mu_1 \pm \mu_2}(\theta)| = \frac{(F_{A_j}^{\sigma_j})^2}{\langle \mu \rangle} \quad (5.45)$$

fixes the relative normalisation between order and disorder operators.

6 Correlation functions

Within the form factor approach, correlation functions are obtained through the spectral sum

$$\begin{aligned} \langle \Phi_1(x) \Phi_2(0) \rangle &= \sum_{n=0}^{\infty} \sum_{a_1, \dots, a_n} \int_{\theta_1 > \dots > \theta_n} \frac{d\theta_1}{2\pi} \dots \frac{d\theta_n}{2\pi} \\ &\quad \langle 0 | \Phi_1(0) | a_1(\theta_1) \dots a_n(\theta_n) \rangle \langle a_n(\theta_n) \dots a_1(\theta_1) | \Phi_2(0) | 0 \rangle e^{-E_n |x|}, \end{aligned} \quad (6.1)$$

where

$$E_n = \sum_{k=1}^n m_{a_k} \cosh \theta_k \quad (6.2)$$

Figure 6: Different approximations of the central charge coming from Eqs. (6.3) and (6.1). The squares indicate the contribution of the states $A_j A_j$ only, the diamonds the inclusion of the states B_2 and $B_1 B_1$, the stars the inclusion of the states B_4 , $B_1 B_3$ and $B_2 B_2$. The exact result is $c = 1$. From right to left, the dashed vertical lines correspond to the first four thresholds where the breather B_n ($n = 1, \dots, 4$) enters the spectrum of asymptotic particles.

Figure 7: A detail of Fig. 6.

denotes the total energy of the n -particle asymptotic state. This large distance expansion can produce good approximations of the integrated correlators even when only few lightest states are included in the sum. A quantitative illustration of the convergence pattern is obtained using the spectral sum to compute exactly known quantities like the central charge c and the scaling dimensions X_Φ through the sum rules [27, 28]

$$c = \frac{3}{4\pi} \int d^2x |x|^2 \langle \Theta(x) \Theta(0) \rangle_c \quad (6.3)$$

$$X_\Phi = -\frac{1}{2\pi \langle \Phi \rangle} \int d^2x \langle \Theta(x) \Phi(0) \rangle_c, \quad (6.4)$$

where $\langle \dots \rangle_c$ denotes connected correlators and $\Theta(x)$ is the trace of the stress-energy tensor. The latter is proportional to the energy operator $\mathcal{E}(x)$ and its form factors are normalised through the condition

$$F_{aa}^\Theta(i\pi) = 2\pi m_a^2. \quad (6.5)$$

Moreover, for $a \neq b$, $P_{ab}^\Theta(\theta)$ factorises a term [26]

$$\cosh \theta + \frac{m_a^2 + m_b^2}{2m_a m_b}. \quad (6.6)$$

The asymptotic condition [28]

$$\lim_{\theta \rightarrow \infty} F_{B_n B_n}^\Theta(\theta) = \frac{(F_{B_n}^\Theta)^2}{\langle \Theta \rangle} \quad (6.7)$$

can be used to determine the expectation value

$$\langle \Theta \rangle = -\pi M^2 \tan \frac{\xi}{2}, \quad (6.8)$$

a result which coincides with that known from the thermodynamic Bethe ansatz (see [29]).

Figures 6 and 7 show the first few approximations provided by the insertion of a truncated spectral sum into the formula (6.3) for the central charge. For this quantity as for the scaling dimensions computed through (6.4), the states $A_j A_j$ yield the exact result at the free fermion point $\beta^2 = 4\pi$, as well as the state $B_1 B_1$ gives the exact result at the free boson point $\beta^2 = 0$. Away from these free points the convergence of the series is extremely rapid due to the factor $|x|^2$ in (6.3) which suppresses the contribution to the integral of the short distances, namely the region where the truncated spectral series fails to reproduce the exact correlator. Hence, in the repulsive region $4\pi < \beta^2 < 8\pi$ the $A_j A_j$ contribution reproduces the exact result with a maximal deviation which is slightly above 1% as $\beta^2 \rightarrow 8\pi$. Entering the attractive region below the free fermion point this contribution falls down quite rapidly as the particles A_j become heavier than the lowest breathers (see (4.3)). The inclusion of the first few breather states, however, gives a quite accurate result also in the repulsive region (Fig. 7).

The same qualitative pattern can be observed in Figs. 8, 9 and 10 showing results for the ratios

$$r_\Phi = \frac{X_\Phi^{approx}}{X_\Phi} \quad (6.9)$$

Figure 8: The ratio (6.9) for the operators μ_j coming from Eqs. (6.4) and (6.1). The squares indicate the contribution of the states $A_j A_j$ only, the diamonds the inclusion of the states B_2 and $B_1 B_1$, the stars the inclusion of the state B_4 .

Figure 9: As in Fig. 8 for the operator $\mathcal{P}^*$.

Figure 10: As in Fig. 8 for the operator $\mathcal{E}$.

between the approximations for the scaling dimensions obtained inserting a truncated spectral series in (6.4) and the exact values. Quantitatively, the absence of the ultraviolet suppressing factor in (6.4) as compared to (6.3) obviously leads to poorer results for a given level of truncation. Of course, the accuracy can be improved by including more states in the spectral sum. Here we simply observe that the increasing deviation from the exact value for larger values of β^2 in the repulsive region is due to the increasing ultraviolet singularities of the exact correlators entering the sum rules, what makes increasingly important the contribution of the short distances to the integrals. The result for $r_{\mathcal{E}} = r_{\Theta}$ is plotted up to the free fermion point because the corresponding integral in (6.4) diverges for $\beta^2 \geq 4\pi$ (see [28]). The integral entering the computation of $r_{\mathcal{P}^*}$ becomes divergent at $\beta^2 = 8\pi$, what helps understanding why the two-particle approximation is particularly poor as this point is approached.

7 Universal ratios

The ability to compute the correlation functions allows the evaluation of the canonical thermodynamic observables. We will consider the magnetisations

$$M_{\sigma} = |\langle \sigma_j \rangle| \quad (7.1)$$

$$M_{\mathcal{P}} = |\langle \mathcal{P} \rangle| \quad (7.2)$$

the specific heat

$$C = \int d^2x \langle \mathcal{E}(x) \mathcal{E}(0) \rangle_c \quad (7.3)$$

the susceptibilities

$$\chi_\sigma = \int d^2x \langle \sigma_j(x) \sigma_j(0) \rangle_c \quad (7.4)$$

$$\chi_{12} = \left| \int d^2x \langle \sigma_1(x) \sigma_2(0) \rangle_c \right| \quad (7.5)$$

$$\chi_{\mathcal{P}} = \int d^2x \langle \mathcal{P}(x) \mathcal{P}(0) \rangle_c \quad (7.6)$$

the second moment correlation lengths

$$\xi_\sigma^{2nd} = \left(\frac{1}{4\chi_\sigma} \int d^2x |x|^2 \langle \sigma_j(x) \sigma_j(0) \rangle_c \right)^{1/2} \quad (7.7)$$

$$\xi_{\mathcal{P}}^{2nd} = \left(\frac{1}{4\chi_{\mathcal{P}}} \int d^2x |x|^2 \langle \mathcal{P}(x) \mathcal{P}(0) \rangle_c \right)^{1/2} \quad (7.8)$$

and the exponential correlation lengths ξ_Φ defined as

$$\lim_{|x| \rightarrow \infty} \langle \sigma_j(x) \sigma_j(0) \rangle_c \sim e^{-|x|/\xi_\sigma} \quad (7.9)$$

$$\lim_{|x| \rightarrow \infty} \langle \mathcal{P}(x) \mathcal{P}(0) \rangle_c \sim e^{-|x|/\xi_{\mathcal{P}}} . \quad (7.10)$$

These quantities can be evaluated on the two sides of the critical line with continuously varying exponents. In the disordered phase II we decompose the above correlators onto the form factors of section 5. Duality is exploited to obtain the results for the ferromagnetic phase I: the operators are replaced by their duals and the correlators are again decomposed over the form factors of section 5; the observables above do not depend on which of the four ferromagnetic ground states is selected by spontaneous symmetry breaking.

For a given observable $\mathcal{F}$, we denote by $\mathcal{F}^+$ its limit toward a given point on the critical line along a path in phase II, and by $\mathcal{F}^-$ the limit toward the same point along the dual path in phase I. Dimensionless numbers independent on metric factors can be obtained suitably combining the limits toward the same fixed point of different observables. These numbers are universal and characterise the scaling region around the critical line with continuously varying exponents.

Some of these universal combinations can be determined exactly. It follows from the spectral decomposition (6.1) that the exponential correlation length ξ_Φ is simply the inverse mass of the lightest asymptotic state coupling to the operator Φ . In the disordered phase the lightest state is A_j for σ_j ; for $\mathcal{P}$ we have instead $A_1 A_2$ in the repulsive region $\beta^2 > 4\pi$ (i.e. $\xi > \pi$) and B_1 in the attractive region. In the ferromagnetic phase, both σ_j and $\mathcal{P}$ (or equivalently μ_j and $\mathcal{P}^*$ in the disordered phase) couple to $A_j A_j$ for $\beta^2 > 8\pi/3$ (i.e. $\xi > \pi/2$) and to B_2 below this threshold. The following universal ratios then follow from (4.3)

$$\frac{\xi_\sigma^+}{\xi_\sigma^-} = \begin{cases} 2, & \xi > \pi/2 \\ 2 \sin \xi, & \xi < \pi/2 \end{cases} \quad (7.11)$$

$$\frac{\xi_{\mathcal{P}}^+}{\xi_{\mathcal{P}}^-} = \begin{cases} 1, & \xi > \pi \\ 1/\sin \frac{\xi}{2}, & \frac{\pi}{2} < \xi < \pi \\ 2 \cos \frac{\xi}{2}, & \xi < \frac{\pi}{2} \end{cases} \quad (7.12)$$

$$\frac{\xi_{\sigma}^+}{\xi_{\mathcal{P}}^+} = \begin{cases} 2, & \xi > \pi \\ 2 \sin \frac{\xi}{2}, & \xi < \pi. \end{cases} \quad (7.13)$$

The fact that the energy operator $\mathcal{E}$ is odd under duality and the specific heat is bilinear in $\mathcal{E}$ implies

$$C^+/C^- = 1. \quad (7.14)$$

The combination

$$C^+ (\xi_{\sigma}^+)^2 = -(1 - \alpha)(2 - \alpha) \frac{\langle \Theta \rangle}{4\pi M^2}, \quad (7.15)$$

where $\alpha = 1 - \frac{\xi}{\pi}$ is the specific heat critical exponent and $\langle \Theta \rangle$ is given in (6.8), is also exact.

The universal ratios involving the susceptibilities and second moment correlation lengths cannot be computed exactly. In Table 4 we list the results provided by the form factor approach including in the spectral series all the one and two-particle states (two-particle approximation). The quantities R_{σ} and $R_{\mathcal{P}}$ are defined as

$$R_{\Phi} = \frac{\chi_{\Phi}^+}{(\xi_{\sigma}^+ M_{\Phi}^-)^2}. \quad (7.16)$$

An important indication about the size of the error involved in the two-particle approximation comes from the comparison with the exact results [30] available for the point $\beta^2 = 4\pi$, where the system reduces to two decoupled Ising models. We stress that, although the theory at this point is free, the operators σ_j and $\mathcal{P}$ belong to the non-trivial sector and have non-zero form factors on an arbitrary number of particles. Hence, the results obtained for their correlators are representative of what happens at generic values of β . Table 5 shows that the error of the two-particle approximation is extremely small (less than 0.1%) for the ratios involving σ_j only, while it grows to order 1% for the ratios involving $\mathcal{P}$. This fact has a very clear origin. The spectral representation we use for the correlators is a large distance expansion and when we truncate it to obtain approximated results we make an error on the ‘short’ distances. Hence, the error on the integrals over all distance scales grows with the strength of the ultraviolet singularities of the correlators, namely with the scaling dimensions of the operators. The scaling dimension of $\mathcal{P}$ is twice that of σ_j at $\beta^2 = 4\pi$ and this explains the two different error scales.

On these grounds we expect that the error on the ratios involving only σ_j will stay quite small along the whole critical line, as a consequence of the fact that the scaling dimension of this operator does not depend on β . Concerning the ratios involving $\mathcal{P}$, the value $X_{\mathcal{P}} = \frac{\beta^2}{16\pi}$ suggests that the error will be of the same size of that of the σ -ratios at $\beta^2 = 2\pi$ and then will

Table 4: Two-particle approximation for the universal ratios along the Ashkin-Teller critical line. The relation between β and the values of the lattice couplings J and J_4 at the corresponding critical point is provided by Eqs. (3.15) and (2.3). The values $\beta^2/\pi = 2, 8/3, 4$ correspond to the 4-state Potts, decoupled Ising and Fateev-Zamolodchikov models, respectively.

Ratio	Two-particle approximation	Exact

R_σ	2	2.00163051..
$\xi_{\mathcal{P}}^{2nd+}/\xi_\sigma^+$	0.408	0.40656..
$\xi_{\mathcal{P}}^{2nd+}/\xi_{\mathcal{P}}^{2nd-}$	1.291	1.3088..
$\chi_{\mathcal{P}}^+/\chi_{\mathcal{P}}^-$	3	2.9108..
$R_{\mathcal{P}}$	0.318	0.32104..

Table 5: Universal ratios at the Ising decoupling point $\beta^2 = 4\pi$.

increase with β to values that (from the results of the previous section) should not exceed 10% at $\beta^2 = 6\pi$.

For $\beta^2 = 2\pi$ the results we obtained should reproduce those for the 4-state Potts model. In order to check this point we label $\alpha = (\alpha_1, \alpha_2)$, with $\alpha_{1,2} = \pm 1$, the four states in which each site of the lattice can be. Then we build out of the Ashkin–Teller spin variables σ_1 and σ_2 the site variable $\sigma = (\sigma_1, \sigma_2)$ and introduce the traditional Potts spin variables

$$\begin{aligned}
s_\alpha(x) &= \delta_{\sigma(x), \alpha} - \frac{1}{4} \\
&= \frac{1}{4}[\alpha_1 \sigma_1(x) + \alpha_2 \sigma_2(x) + \alpha_1 \alpha_2 \sigma_1 \sigma_2(x)]
\end{aligned} \tag{7.17}$$

satisfying $\sum_\alpha s_\alpha = 0$. If we denote by $|0_\gamma\rangle$ the ground state that spontaneous symmetry breaking has selected in the ferromagnetic phase I, we will have

$$\begin{aligned}
\langle 0_\gamma | s_\alpha(x) s_\alpha(0) | 0_\gamma \rangle &= \frac{1}{16} \langle 0_\gamma | \sigma_1(x) \sigma_1(0) + \sigma_2(x) \sigma_2(0) + \sigma_1 \sigma_2(x) \sigma_1 \sigma_2(0) + 2\alpha_1 \alpha_2 \sigma_1(x) \sigma_2(0) \\
&+ 2\alpha_2 \sigma_1(x) \sigma_1 \sigma_2(0) + 2\alpha_1 \sigma_2(x) \sigma_1 \sigma_2(0) | 0_\gamma \rangle .
\end{aligned} \tag{7.18}$$

Along the Potts trajectory the internal symmetry is enhanced to invariance under global permutations of the four colours and one finds the expression

$$\begin{aligned}
\langle 0_{(1,1)} | s_\alpha(x) s_\alpha(0) | 0_{(1,1)} \rangle_{Potts} &= \\
\frac{1}{16} \langle 0_{(1,1)} | 3\sigma_1(x) \sigma_1(0) + 2(\alpha_1 \alpha_2 + \alpha_2 + \alpha_1) \sigma_1(x) \sigma_2(0) | 0_{(1,1)} \rangle_{Potts} &= \\
\frac{1}{16} \langle 0_{(1,1)} | 3\sigma_1(x) \sigma_1(0) + 2(4\delta_{\alpha, (1,1)} - 1) \sigma_1(x) \sigma_2(0) | 0_{(1,1)} \rangle_{Potts} &
\end{aligned} \tag{7.19}$$

explicitely showing that only the cases $\alpha = \gamma$ and $\alpha \neq \gamma$ are distinguished in the correlator $\langle 0_\gamma | s_\alpha(x) s_\alpha(0) | 0_\gamma \rangle$. In the disordered phase mixed correlators vanish by symmetry and we have

$$\langle s_\alpha(x) s_\alpha(0) \rangle_{Potts} = \frac{3}{16} \langle \sigma_1(x) \sigma_1(0) \rangle_{Potts} . \tag{7.20}$$

In the Potts model we define⁴ the longitudinal spontaneous magnetisation

$$M = \langle 0_\alpha | s_\alpha | 0_\alpha \rangle, \quad (7.21)$$

the high-temperature susceptibility

$$\chi = \int d^2x \langle s_\alpha(x) s_\alpha(0) \rangle_c, \quad (7.22)$$

the low-temperature longitudinal and transverse susceptibilities

$$\chi_L = \int d^2x \langle 0_\alpha | s_\alpha(x) s_\alpha(0) | 0_\alpha \rangle_c \quad (7.23)$$

$$\chi_T = \int d^2x \langle 0_\alpha | s_\gamma(x) s_\gamma(0) | 0_\alpha \rangle_c \quad \alpha \neq \gamma \quad (7.24)$$

and the second moment and exponential correlation lengths ξ^{2nd} and ξ computed from the correlator $\langle s_\alpha(x) s_\alpha(0) \rangle$ at high temperature and $\langle 0_\alpha | s_\alpha(x) s_\alpha(0) | 0_\alpha \rangle$ at low temperature.

The relations between these quantities and the Ashkin-Teller observables follow from Eqs. (7.17), (7.19) and (7.20). In particular one obtains

$$\chi^+ / \chi_L^- = \left[\frac{\chi_\sigma^+ / \chi_\sigma^-}{1 + 2\chi_{12}^- / \chi_\sigma^-} \right]_{\beta^2=2\pi} \simeq 4.02 \quad (7.25)$$

$$\chi_T^- / \chi_L^- = \left[\frac{1 - \frac{2}{3}\chi_{12}^- / \chi_\sigma^-}{1 + 2\chi_{12}^- / \chi_\sigma^-} \right]_{\beta^2=2\pi} \simeq 0.129. \quad (7.26)$$

These results agree⁵ with those of Refs. [31, 32] where the amplitude ratios for the q -state Potts model were computed. This non-trivial check eliminates the doubt raised in [32] about the result of [31] for the ratio χ^+ / χ_L^- in the q -state Potts model. For $q = 3$ full agreement with the theoretical prediction was found in the lattice studies of Refs. [33, 34].

8 Conclusion

We have computed the universal ratios along the Ashkin-Teller critical line with continuously varying exponents using the field theoretical description of the scaling limit provided by the sine-Gordon model. As discussed in the Introduction, these results can be tested through numerical simulation or series expansions on the lattice model. Up to now, lattice results for the universal ratios along the Ashkin-Teller critical line exist only for the particular cases of the Ising decoupling point (where the exact values are known, see Table 5) and of the 4-state Potts model [35, 34]. In the latter case the lattice results are compatible with the field theoretical predictions but are affected by large uncertainties originated by logarithmic corrections to scaling [36, 37] coming from the marginal operator that is responsible for the end of critical line at the

⁴We drop the subscript *Potts* on the correlators below.

⁵There is a slight deviation from the values quoted in Refs. [31, 32] due to the fact that the contributions of the states $A_j B_2$ and $B_2 B_2$ had been neglected in those works.

Potts point. Reducing the error bars at this point as well as obtaining estimates at other points along the Ashkin-Teller critical line appear as challenging tasks for future lattice studies.
